1 This paper is distributed solely for the purpose of pre-dissemination peer review and must not be  
2 disclosed, released, or published until after approval by the U.S. Geological Survey (USGS). It is  
3 deliberative and pre-decisional information and the findings and conclusions in the paper have not  
4 been formally approved for release by the USGS. It does not represent and should not be  
5 construed to represent any USGS determination or policy.  
6

Bureau Approval Review for the Director, U.S. Geological Survey, on manuscript IP-031729. Review conducted by K.J. Breen, BAO.

Excellent review by Scott Wright and *Earth Surface Processes and Landforms* journal reviewers. Responses to the reviewers are thorough and have led to improvements in the revised manuscript. Readiness review (Hainly) and responses also are well done.

With open-source release of the software through the USGS hydroacoustics Web page comes the need to associate an appropriate disclaimer and software user rights notice. See guidance on these points and a note on journal copyright in my approval memo. Approved as a journal article on May 7, 2012.

### Abstract

The use of acoustic Doppler current profilers (ADCP) for discharge measurements and three-dimensional flow mapping has increased rapidly in recent years and has been primarily driven by advances in acoustic technology and signal processing. Recent research has developed a variety of methods for processing data obtained from a range of ADCP deployments and this paper builds on this progress by describing new software for processing and visualizing ADCP data collected along transects in rivers or other bodies of water. The new utility, the Velocity Mapping Toolbox (VMT), allows rapid processing (vector rotation, projection, averaging and smoothing), visualization (planform and cross-section vector and contouring), and analysis of a range of ADCP-derived datasets. The paper documents the data processing routines in the toolbox and presents a set of diverse examples that demonstrate its capabilities. The toolbox is applicable to the analysis of ADCP data collected in a wide range of aquatic environments and is made available as open-source code along with this publication.

Any use of trade, product, or firm names is for descriptive purposes only and does not imply endorsement by the U.S. Government.

## 1.0 Introduction

Over the past 20 years, acoustic Doppler Current Profilers (ADCPs) have revolutionized the measurement of flow and discharge in open channels (cf. Gordon, 1989; Simpson and Oltman, 1993; Oberg and Mueller, 1994). The reliability and efficiency of ADCPs for obtaining accurate discharge measurements (Morlock 1996; Oberg and Mueller, 2007) are widely acknowledged and ADCPs are used routinely by many agencies and environmental consultants worldwide to measure and record discharge in inland waterways, rivers, lakes, and estuaries. In 2010, the U.S. Geological Survey (USGS) utilized hydroacoustic instrumentation for approximately 69% of all discharge measurements for stream gauging across the United States. Of these, approximately 82% of non-wading discharge measurements were made using ADCPs (Garcia et al., 2012).

Not only do ADCPs provide rapid, accurate measurements of discharges in flowing bodies of water, but these instruments also are increasingly being used in scientific research to characterize the spatio-temporal patterns of flow in various types of water bodies (e.g. Wagner and Mueller, 2001; Muste et al., 2004a; Jacobson et al., 2004; Dinehart and Burau 2005a,b; Parsons et al., 2005, 2007; Szupiany et al., 2009; Jackson et al., 2009; Czuba et al., 2011; Wright and Kaplinski, 2011; Riley and Rhoads, 2012). Indeed, the extensive three-dimensional velocity data provided by ADCPs allow for detailed characterization of complex flow fields in natural rivers and the relation of these flow fields to extant or changing channel boundaries (e.g. Parsons et al., 2005; Szupiany et al., 2009; Wright and Kaplinski, 2011; Riley and Rhoads, 2012). Recent applications and deployments of ADCPs have also shown how these instruments can yield data on turbulence characteristics (e.g. Droz et al., 1998; Stacey et al., 1999; Lu and Lueck, 1999; Nystrom et al., 2007), suspended sediment concentration dynamics (through use of acoustic backscatter) (e.g. Gartner, 2004, Kostaschuk et al., 2004, Dinehart and Burau, 2005a,b; Wall et al., 2006; Topping et al., 2006; Shugar et al., 2010), spatial variations in shear-stress (Sime et al., 2007), and bedload transport rates (through quantification of a moving bed condition and the differences detectable between the instrument-derived boat velocity from bottom track and GPS-derived boat velocity) (Rennie et al., 2002; Rennie and Millar, 2007; Jamieson et al., 2009) Thus, ADCPs have become multipurpose instruments for examining flow, morphology and sediment flux, thereby demonstrating considerable promise for improved process-based understanding of geophysical processes in a wide range of aquatic environments (Best et al., 2005; Parsons et al., 2005; Garcia et al., 2007; Bartholomä et al. 2009; French et al. 2008; Jackson et al. 2008; Lane et al. 2008; Kostaschuk et al. 2009, 2010; Shugar et al. 2010; Wright and Kaplinski, 2011).

The increasing use of ADCPs to explore the characteristics of complex natural flows has led to a need for post-processing methods for managing, evaluating, analyzing, and displaying three-dimensional velocity data. Methods for processing ADCP time series data from fixed bed (up-looking orientation) moorings (c.f. Côté et al., 2011; Donovan 2004) have been in existence for some time. A number of data processing techniques for moving-vessel deployments have been described and most involve collection of data along transects (e.g. Muste et al., 2004a; Dinehart

1  
2 85 and Burau, 2005a,b; Szupiany et al., 2007, 2009). However, many of these methods are designed  
3 86 for singular purposes and have limited flexibility in their application. For example, Le Bot et al.  
4 87 (2011) present a methodology, called CASCADE, for extracting ADCP data collected in marine  
5 88 environments along vessel transects and outline a routine to derive spatially-averaged velocities  
6 89 along such transects. However, because ADCP data collected from single transects across an  
7 90 open-channel often contain substantial noise and variability, accurate characterizations of three-  
8 91 dimensional velocity patterns typically require compositing of data from repeat transects (Szupiany  
9 92 et al. 2007, 2009). Dinehart and Burau (2005a,b) presented a method in which multiple transects  
10 93 can be projected and averaged onto a 2D planar grid to allow analysis of the 3D flow field, whereas  
11 94 Rennie and Church (2010) developed a procedure whereby spatially-distributed ADCP data can be  
12 95 interpolated onto a planar-horizontal 2D grid covering large areas up to entire channel reaches.  
13 96 Although both of these methods hold significant promise, specifically in terms of aiding  
14 97 geomorphological interpretations of measured flow processes, the methods have been developed  
15 98 for specific applications and are not widely available to the earth-science community. A  
16 99 commercially-available tool, LOG\_aFlow® (e.g. Müller et al., 2001), is available and allows for  
17 100 interpolation of ADCP-derived velocity onto 2D horizontal planes and 3D volumes using  
18 101 hydrodynamic interpolation in space and time. However this tool is not specifically designed for  
19 102 mapping of cross-section data, which are often used for analysis of morphodynamic and  
20 103 geomorphological flow processes (e.g. Dinehart and Burau, 2005a,b; Parsons et al., 2007;  
21 104 Szupiany et al., 2009). Kim et al. (2007) developed AdcpXP, a post-processing software package  
22 105 for ADCP data that includes spatial- and depth-averaging routines, in addition to scripts for  
23 106 computation of bulk flow parameters, turbulence parameters, and dispersion coefficients. A freely-  
24 107 available software tool, called VMS, includes analytical capabilities for quality assurance of  
25 108 moving-vessel, multiple-transect ADCP data, with the general aim of improving processing and  
26 109 visualization of large, reach-scale ADCP data sets for comparison with results of numerical and  
27 110 physical models (Kim et al., 2009). While useful, none of these ADCP data-processing packages  
28 111 computes three-dimensional velocity components, including components used to identify  
29 112 secondary flow, using techniques employed by the geomorphological process community. To this  
30 113 end, the need exists for an analytical technique for amalgamating velocity data from multiple ADCP  
31 114 transects to produce a composite depiction of three-dimensional velocity fields at channel cross-  
32 115 sections. Herein, we present a new software tool, the Velocity Mapping Toolbox (VMT), to address  
33 116 this need.

34 117 VMT is a Matlab®-based toolbox for processing, analyzing, and displaying cross-sectional  
35 118 velocity data collected along multiple ADCP transects. Input to VMT consists of ASCII output files  
36 119 from the ADCP data-collection software (Teledyne RD Instruments, 2009). The software projects  
37 120 data collected along several irregular ship tracks, or measurement transects, onto a straight-line  
38 121 plane that defines a measurement cross-section. The velocity data from individual transects are  
39 122 then averaged to produce a composite representation of the cross-sectional flow field. The

1  
2 123 software can be used to explore patterns of three-dimensional fluid motion through several  
3 124 methods for calculation of secondary flows (e.g. Rhoads and Kenworthy, 1998; Lane et al., 2000),  
4 125 a defining feature of VMT setting it apart from other available software. The software also includes  
5 126 capabilities for analyzing the acoustic backscatter, bathymetric, and temperature data obtained  
6 127 from an ADCP. A user-friendly graphical user interface (GUI) enhances program functionality and  
7 128 provides ready access to two- and three-dimensional plotting functions, allowing rapid display and  
8 129 interrogation of velocity, backscatter, and bathymetry data. This paper describes the basic  
9 130 processing methods employed by VMT and highlights some of the capabilities of the toolbox  
10 131 through three example applications.

## 134 **2.0 Acoustic Doppler Current Profilers (ADCP)**

135 Detailed background information on the principles of acoustic Doppler current profilers can be  
136 found in Mueller and Wagner (2009), Simpson (2001), and Gordon (1996). In brief, the ADCP uses  
137 acoustic physics to measure the three-dimensional velocity of flowing water in fluvial, lacustrine,  
138 estuarine, coastal, and marine environments. It does so by transmitting an acoustic signal, at a  
139 known frequency, into the water column and recording the detectable acoustic backscatter from  
140 small particles suspended and carried within the flow field, and that are assumed to be moving at  
141 the same velocity as the water. The measurable Doppler shift in acoustic frequency (and/or the  
142 phase-amplitude of superimposed pulses) of this backscattered signal is then used to measure  
143 fluid velocity along the beam path. The backscatter signal received from the acoustic pulse  
144 traveling through the water column is gated over a range (time) to produce successive segments,  
145 called bins, along each of four (three in some systems) acoustic beams. Bins thus represent  
146 discrete measurement volumes for velocities at different depths over the water column. Because  
147 the individual beams are oriented in different directions, velocity components that are oriented  
148 orthogonally to one another can be measured under the assumption that water currents are  
149 uniform (homogeneous) across layers at a constant depth over the footprint of the acoustic beams.  
150 A trigonometric transformation is employed to compute three-dimensional velocity components  
151 within a Cartesian coordinate system. This process generates vertical profiles, or ensembles, of  
152 three-dimensional velocity components over the flow depth. The ensemble sampling rate is a  
153 function of the flow depth and frequency and configuration of the instrument, but can be as high as  
154 5 Hz (many instruments sample at a higher frequency and internally average this data to reduce  
155 noise). ADCPs can be deployed at a fixed location (e.g. a surface mooring or a bed-mounted and  
156 up-looking configuration), whereby profiles of three-dimensional velocity are obtained as a time  
157 series, or from a moving vessel, whereby velocity data are collected as spatial transects  
158 (longitudinal or cross-sectional). This paper focuses on the latter application.  
159  
160

159

160

### 3.0 The Velocity Mapping Toolbox (VMT): An Overview

VMT is accessed through a graphical user interface (GUI) (Fig. 1) and is currently only capable of reading ADCP data files in ASCII format exported from WinRiver II data-collection software provided by the ADCP manufacturer Teledyne RD Instruments. Data files should be quality-assured using WinRiver II, or other software packages, and then imported into VMT as individual transects or, as is now often the case for velocity mapping (e.g. Szupiany et al., 2009), as groups of repeat transects for a single cross-section (Fig. 2). Presently (2012), VMT utilizes only measured velocity data in all computations and no attempt is made in VMT to account for unmeasured areas near the bed, surface, and transect edges.

Once the velocity data are pre-processed and quality assured in WinRiver II, they are imported into VMT as ASCII files and several computational steps are performed automatically (Fig. 3). First, either a mean cross-section orientation is calculated from data for a set of transects or, if the user prefers, this calculated cross-section can be replaced by a cross-section with a user-defined orientation and length (Fig. 3 – Step 1). The horizontal and vertical dimensions of an interpolation grid are then defined for the cross-section. In Step 2 (Fig. 3), velocity data from each individual transect are projected onto the cross-section using an anisotropic projection method and the projected data are interpolated onto the defined cross-section grid (Fig. 3 – Step 3). In this step, the user has the option to apply a correction to the observed velocities to account for potential streamwise variations in depth between locations of the observation points and the mapped points, assuming a constant streamwise mass flux (Hoitink et al. 2009). This simple correction scales the observed streamwise velocity in each bin by the ratio of the water column depth at the observation point and the depth of the mean cross-section at the projected observation point. The projected and interpolated velocity data for the set of transects are then averaged over the grid (Fig. 3 – Step 4), to produce a mean representation of the velocity field for the cross-section. Finally, the averaged three-dimensional velocity components for the cross-section are used to compute other metrics, such as the orientation and magnitude of velocity vectors and secondary flow by means of user-selectable methods. Once these computations are complete, a variety of user-defined options are available for smoothing and plotting the data. The following section describes each of these steps in detail.

### 4.0 VMT Data Averaging Routines

#### 4.1 Defining an Average Cross-Section Orientation

Two methods can be used to define the orientation of a cross-section onto which data for individual transects will be mapped: 1) fitting of positions (UTM coordinates) of velocity profiles (ensembles) using least squares regression, and 2) using user-supplied UTM coordinates for endpoints of the cross-section. The first option is the default and is performed automatically unless the user specifies option two. When used with a global positioning system (GPS), as is normally

1  
2 199 recommended for velocity mapping applications and discharge measurements with moving-bed  
3 200 conditions (e.g. Mueller and Wagner 2009), each vertical profile of three-dimensional ADCP  
4 201 velocity data, or ensemble, is automatically georeferenced during data collection. VMT transforms  
5 202 the recorded latitude and longitude coordinate data for each ADCP ensemble into an easting and  
6 203 northing in Universal Transverse Mercator (UTM) coordinates, automatically selecting the correct  
7 204 UTM zone. In the first method, the toolbox determines a mean cross-section orientation for a set of  
8 205 individual transects (ship tracks) by fitting a least squares regression line through the UTM  
9 206 positions of every ensemble in a set of transects (Fig. 2). Data are compiled from all repeat  
10 207 transects and the GPS positions of every ensemble (velocity profile) are used in the regression  
11 208 analysis to define a line that best represents the linear pattern of the data cloud (Fig. 2 and Fig. 3 –  
12 209 Step 1). The endpoints of the resulting cross-section are defined by the limits of the data cloud to  
13 210 ensure that the line spans the entire extent of the measured data. This method best represents the  
14 211 overall pattern of the set of ship tracks and is most appropriate when performing a single survey at  
15 212 a site.

16  
17 213 When repeat surveys are conducted along a pre-determined line representing the cross-  
18 214 section, the user may wish to map velocity data onto this line to ensure that comparisons of  
19 215 velocity fields between different dates are consistent, i.e. that all the fields are mapped onto a  
20 216 plane with a fixed orientation relative to the channel alignment. Because the cross-section  
21 217 orientation produced by the best-fit method will vary slightly between surveys, no matter how  
22 218 accurate the boat navigation is, and because small differences in cross-section orientation can  
23 219 affect the magnitudes of secondary flows, using the fixed endpoints option might be preferable for  
24 220 comparing changes in three-dimensional flow structure between different measurement campaigns.  
25 221 However, care should be taken when using this method to ensure that projecting the repeat  
26 222 transects onto a user-defined cross-section is reasonable, given the position and alignment of the  
27 223 transects relative to the cross-section.

28  
29 224

#### 30 225 *4.2 Defining the Interpolation Grid*

31 226 The horizontal spacing of ensembles along each moving-vessel transect differs because of  
32 227 changes in boat speed. Moreover, ensembles in different transects are not usually spatially  
33 228 coincident. To overcome these issues, a uniform grid for interpolation of data is generated along  
34 229 the cross-section line (Fig. 2 and Fig. 3 – Step 1). The horizontal resolution of the grid is user-  
35 230 specified (default = 1 m) and the vertical resolution equals the vertical dimension of the ADCP bins  
36 231 (i.e. bin size). Whereas the cross-section defines the plane onto which data will be projected, the  
37 232 grid defines the nodes on this plane onto which data will be interpolated.

38 233

#### 39 234 *4.3 Projecting Transect Data onto the Plane of the Cross-Section*

40 235 The next step in the transect-averaging procedure is to project data from individual transects onto  
41 236 the plane of the cross-section (Fig. 3 – Step 2). Virtually all ship tracks defining individual transects

237 are irregular and deviate both in position and length from the plane of the cross-section. Projection  
 238 of the velocity vector data from the irregular transects onto the straight-line plane of the cross-  
 239 section is accomplished through an orthogonal translation of the data point from its original location  
 240  $(X, Y)$  to a point on the cross-section line  $(X_{proj}, Y_{proj})$ . This orthogonal projection occurs along a line  
 241 that is perpendicular to the cross-section line and passing through the data point of interest. The  
 242 projected co-ordinates of a point on the mean cross-section for a point originally located at  $(X, Y)$   
 243 are given by

$$X_{proj} = \frac{X - mb + mY}{m^2 + 1} \quad (1)$$

$$Y_{proj} = \frac{b + mX + m^2Y}{m^2 + 1} \quad (2)$$

249 where  $m$  and  $b$  are the slope and intercept of the cross-section line. This transformation is  
 250 completed for every ensemble in a transect, thereby projecting a dataset along an irregular ship  
 251 track onto the straight line of the cross-section. This projection routine is repeated for every  
 252 transect loaded into VMT for the cross-section under analysis. Users are responsible for ensuring  
 253 that the loaded transects are representative of the cross-section and mapping of the data to the  
 254 straight line of the cross-section is a valid assumption (including data in transects lying too far off  
 255 the line that can result in the introduction of errors in reaches with variable bathymetry and flow  
 256 distributions).

#### 258 *4.4 Interpolating Individual Transect Data to the User-Specified Grid Nodes*

259 The next step is to interpolate projected data from individual transects onto the grid nodes in the  
 260 cross-section. To accomplish this task, a linear interpolation scheme is applied to each individual  
 261 transect (Fig. 3 – Step 3). Care must be taken when choosing the horizontal grid-node spacing to  
 262 ensure this spacing is appropriate for the data set: choosing too large a grid node spacing will  
 263 result in a coarse horizontal resolution of the velocity field, while choosing too small a spacing will  
 264 lead to excessive interpolation where ensembles are widely-spaced. VMT defaults to a 1 m  
 265 spacing and also automatically computes a recommended minimum grid node spacing, which  
 266 equals the median plus one standard deviation of the projected ensemble spacing along the cross-  
 267 section for all the transects. This recommendation is provided to help the user define an optimum  
 268 grid node spacing for a data set.

#### 270 *4.5 Averaging the Transect Data at Each Grid Node*

271 The projected and interpolated velocity data for all transects are averaged at every grid node in the  
 272 cross-section to obtain a composite representation of the velocity field (Fig. 3 – Step 4). A simple

1  
2 273 arithmetic mean is applied for each of the basic velocity components (east, north, and vertical  
3 274 velocities) and for acoustic backscatter and bed depth. After averaging is complete for all grid  
4 275 nodes, a coordinate rotation is applied to transform velocity components in basic (Earth)  
5 276 coordinates into velocity components in the plane of the cross-section. This transformation yields  
6 277 mean streamwise (U, positive downstream), cross-stream (V, positive to the left bank) and vertical  
7 278 (W, positive up) velocity components for every grid node. These velocity components, in turn, are  
8 279 used to compute two-dimensional velocity vector magnitudes and orientations for the set of grid  
9 280 nodes.  
10  
11  
12  
13

281

#### 15 282 *4.6 Rotation Schemes, Secondary Flow Vectors, and Depth-Averaged Velocities*

17 283 Several coordinate rotation schemes are used in VMT to calculate different types of primary and  
18 284 secondary velocity components. The definitions of the primary and secondary velocity  
19 285 components depend on the rotation scheme used in the computation (see Lane et al., 2000 for a  
20 286 detailed explanation). All of these schemes involve rotating horizontal planes of the flow around  
21 287 the vertical axis of the cross-section. In no case is the vertical plane of the flow rotated around the  
22 288 horizontal axis; thus, W remains unchanged in these rotations. Initially the software rotates data  
23 289 collected by the ADCP in a northing-easting frame of reference into the plane of the cross-section.  
24 290 This scheme is referred to as the “no rotation” scheme and generates velocity components  
25 291 oriented orthogonal to the cross-section (U), parallel to the cross-section in the horizontal direction  
26 292 (V) and parallel to the plane of the cross-section in the vertical direction (W). The zero net  
27 293 secondary discharge method reorients the cross-section so that the net discharge in the lateral  
28 294 plane of the rotated cross-section equals zero (Markham and Thorne, 1992) to yield  $U_{zsd}$  and  $V_{zsd}$ .  
29 295 The Rozovskii method involves rotating each individual ensemble around its vertical axis to obtain  
30 296 zero net secondary discharge over the ensemble (Rozovskii, 1957) to yield  $U_{roz}$  and  $V_{roz}$ . The  
31 297 primary and secondary velocities derived from the Rozovskii method are also decomposed into  
32 298 downstream and cross-stream components of  $U_{roz}$  and  $V_{roz}$  relative to the orientation of the channel  
33 299 cross-section (Rhoads and Kenworthy, 1998).  
34  
35  
36  
37  
38  
39  
40  
41  
42

43 300 The different types of secondary velocity components are used along with the vertical  
44 301 velocity component to compute the orientation and magnitude of the secondary flow vectors. The  
45 302 basic formulae for these computations are:  
46  
47  
48  
49  
50

303

304

$$51 \quad 305 \quad S_m = \sqrt{L_c^2 + W^2} \quad (3)$$

$$52 \quad 306 \quad S_\theta = \tan\left(\frac{W}{L_c}\right)^{-1} \quad (4)$$

307

308

309

310

311

312

309 where  $S_m$  is the vector magnitude,  $S_\theta$  is the vector orientation,  $W$  is the vertical velocity component  
 310 and  $L_c$  is a lateral velocity component ( $V$ ,  $V_{zsd}$ , or  $V_{roz}$ ). Secondary flow vectors calculated using  
 311 horizontal velocity components from various rotation methods provide different perspectives on the  
 312 characteristics of secondary flow (Rhoads and Kenworthy, 1999; Lane et al., 2000).

313 VMT also has the capability to compute depth- and layer-averaged velocities. In both cases,  
 314 the average is computed by

315

$$316 \quad V_{LA} = \frac{1}{d_2 - d_1} \int_{d_1}^{d_2} v dz \quad (5)$$

317

318 where  $V_{LA}$  is the depth- or layer-averaged velocity,  $v$  is the north or east component of velocity  
 319 (averaged independently), and  $d_1$  and  $d_2$  are the lower and upper limits of the depth range used in  
 320 averaging, respectively. For layer-averaging, the user specifies  $d_1$  and  $d_2$  in the VMT interface.  
 321 For depth-averaging, inputs for  $d_1$  and  $d_2$  are left blank and VMT computes the average over the  
 322 full depth of measured flow. A separate layer average,  $V_{LA}$ , is computed for the north component  
 323 and the east component of velocity at each grid node and then the two components are used to  
 324 compute the magnitude and direction of the two-dimensional, layer-averaged velocity vectors.

325 It is important to note that an ADCP cannot measure near the bed or near the surface  
 326 because of side-lobe interference, transducer ringing, flow disturbance, and the ADCP immersion  
 327 depth. VMT does not estimate velocities in these unmeasured zones by extrapolating velocity data  
 328 to the bed or to the surface. Therefore, depth-averaging in VMT is performed only over the  
 329 measured vertical extent of the data. If the combination of the ADCP configuration and site  
 330 conditions allow only a limited portion of the total water column to be measured, the depth-  
 331 averaged velocity from VMT may not be representative of the true depth-averaged velocity.

332

#### 333 *4.7 Spatial Averaging and Smoothing*

334 Transect averaging is used to approximate temporal averaging when performing moving-boat  
 335 ADCP measurements. This pseudo-temporal averaging represents an improvement over single  
 336 passes, but averaged data often still contain uncertainties related to instrument noise and turbulent  
 337 fluctuations in velocities that can obscure overall flow patterns, especially the patterns of  
 338 secondary flow. Smoothing of the velocity data through spatial averaging can help reduce local  
 339 variability in the data, so that overall patterns of fluid motion can be clearly discerned.

340 VMT allows the user to spatially-average data both in plan view as well as in cross-sections  
 341 using a moving average and a user-specified window size. The spatial averaging (or smoothing)  
 342 routines used within VMT are simple moving-averages that work in one (planform) and two (cross-  
 343 section) dimensions (Fig. 4). The user has complete control of the window size for the spatial  
 344 averaging. In the VMT interface, the user specifies the half window size, i.e. the number of grid  
 345 nodes  $n$  on either side of a point to include in averaging (planform). Setting the smoothing window

1  
2 346 parameter to a value of  $n$  will replace the velocity at a point with the average of the point and  $n$   
3 347 neighbouring points on either side of the point. For plan-view plots, the averaging is applied in a  
4 348 cross-stream direction only (depth- or layer-averaging is applied in the vertical). For cross-section  
5 349 data, the user specifies both a horizontal smoothing window size,  $n_h$ , and a vertical smoothing  
6 350 window size  $n_v$ . Setting these parameters ( $n_h$ , and  $n_v$ ) to zero results in no spatial averaging. The  
7 351 routines ignore missing/invalid data, and data near the edges are averaged using only the  
8 352 available data within the averaging window. The total width of an averaging window can be  
9 353 computed by multiplying the grid node spacing by twice the half window size.  
10  
11  
12  
13  
14 354

#### 15 355 *4.8 Plotting Capabilities*

16  
17 356 VMT includes complete plotting capabilities for depicting ADCP data in planform and cross-  
18 357 sectional views. Planform views are used to depict depth- or layer-averaged flow vectors (depth  
19 358 averaged over the measured profile only). Cross-sectional views include colour-based contour  
20 359 plots of a variety of velocity, backscatter, and flow direction data with the capability to superimpose  
21 360 secondary velocity vectors on these plots (e.g. see later Fig. 10). The backscatter intensity data  
22 361 used in VMT are those exported from the data collection software (WinRiver II), which have been  
23 362 adjusted for beam spread and adsorption (Teledyne RD Instruments, 2009). VMT users should  
24 363 thus verify that the backscatter values computed and exported from the software are suitable for  
25 364 their application.

26 365 VMT provides numerous options for plotting, some of which are discussed in the examples  
27 366 shown below. VMT also automatically calculates values for all variables during data input; thus,  
28 367 once the data are loaded, analysis of flow patterns can proceed by selecting different combinations  
29 368 of variables to display on cross-sectional plots and by choosing different levels of smoothing for  
30 369 these plots. New plots are generated rapidly because the program does not have to compute any  
31 370 new variables to produce alternative displays of the data.

### 43 373 **5.0 Results**

44 374 Three example applications are presented to illustrate some of the capabilities of VMT. The three  
45 375 applications include processing and visualization of ADCP measurements from: i) the Upper St.  
46 376 Clair River, the primary outlet from Lake Huron (MI, USA); ii) the Wabash-Embarras River  
47 377 confluence (IL, USA); and iii) Clinton Lake (IL, USA). For reference, Table 1 contains the  
48 378 processing and visualization parameters entered in the VMT interface to generate the associated  
49 379 figures for each site. Minor editing of the figures outside of VMT has been completed for  
50 380 publication (e.g. addition of scale bars, section numbers, and labels).

#### 57 382 *5.1 Upper St. Clair River*

1  
2 383 The Upper St. Clair River is the primary outlet for Lake Huron, which drains the upper Great Lakes  
3 384 into the Lake St. Clair-Lake Erie system. A field survey was conducted during July 2 - July 25,  
4 385 2008, using a 19-foot aluminum work vessel (*R/V Sangamon*) and was part of the International  
5 386 Upper Great Lakes study into the possible impacts of the St. Clair River on lake levels (see Czuba  
6 387 et al., 2011). The survey was conducted with a 1200 kHz ADCP mounted near the bow on the port  
7 388 side of the boat. The ADCP was integrated with a Leica System 1230 differential Global  
8 389 Positioning System (dGPS) that provided real-time kinematic (RTK) position information at a  
9 390 relative accuracy of 0.02 m at 5 Hz. A series of eighteen cross-sections were established for data  
10 391 collection and at least 6 ADCP transects were obtained at each cross-section.

11 392 A planform view of the depth-averaged velocity vectors through the reach for each of the 18  
12 393 cross-sections highlights the convergence and acceleration of the lake outflow into the Upper St.  
13 394 Clair River, the development of a large region of flow separation on the east bank downstream of  
14 395 the main constriction (eastern side of cross-sections 9-12) and deceleration of the flow as the  
15 396 channel widens at the downstream end of the survey reach (Fig. 5). Detailed views of the three-  
16 397 dimensional flow within one of the cross-sections (cross-section 9) shows data for individual  
17 398 transects that have been interpolated and averaged onto a regular grid, and then spatially-  
18 399 averaged for 1, 2, 4, 6, and 8 transects using VMT. The resulting velocity vectors have been  
19 400 rotated to the cross-section orientation within VMT, giving primary flow and secondary flow based  
20 401 on the zero secondary discharge definition. The primary velocity ( $U_{zsd}$ ) is shown as a colour  
21 402 contour plot (Fig. 6) and the arrows represent the magnitude and orientation of the secondary  
22 403 velocity vectors ( $V_{zsd}$ ,  $W$ ). The vertical scale of the plot is exaggerated to clearly visualize the  
23 404 velocity field and the number of secondary velocity vectors plotted has been constrained to avoid  
24 405 excessive clutter (using options available within the VMT interface).

25 406 The comparison of averaging based on different numbers of transects highlights the  
26 407 influence of additional information on patterns of secondary flow (Fig. 6). The plot of the data from  
27 408 a single transect contains considerable local variability in the pattern of secondary velocity vectors  
28 409 (Fig. 6a). For example, large coherent turbulent structures of similar magnitude and scale, yet  
29 410 opposite direction, were seen in transects 1 (Fig. 6a) and 6 (not shown individually) above the  
30 411 scour hole near the left bank. As additional transects are included in the averaging, the secondary  
31 412 flow field becomes increasingly visible (Fig. 6b-e) due to averaging of large-scale turbulent eddies  
32 413 (e.g. Muste et al., 2004a,b; Szupiany et al., 2007) and instrument noise recorded in each of the  
33 414 individual transects.

34 415 The appearance of velocity data within the side-lobe interference band (zone of missing  
35 416 data near the bed) at 290 m in the cross-section in Figure 6c-e results from the inclusion of  
36 417 transect 4 in the averaging process. Transect 4 deviated up to 30 meters downstream of the  
37 418 measurement section, and deeper water within the scour hole on the right bank (see Fig. 5 inset)  
38 419 led to deeper velocity measurements compared to the other transects. Velocity data imposing into  
39 420 the side-lobe band is a tell-tale sign of variable depths between transects and can result in the

1  
2 421 introduction of error. Users should either omit the erroneous transects (as in Czuba et al. 2011) or  
3 422 carefully review the results using VMT (averaging data with and without the problem transect) to  
4 423 ensure that the inclusion of the data does not introduce significant error into the average velocity  
5 424 distribution. For the present example, the inclusion of transect 4 introduces some error into the  
6 425 average velocity distribution for this section primarily near the bed at about 290 m across the  
7 426 cross-section, but it does not significantly alter the overall pattern of secondary circulation. While  
8 427 the pattern of the secondary flow field remains relatively constant between the six-transect average  
9 428 (Fig. 6d) and eight-transect average (Fig. 6e), the sudden jump in magnitude of the secondary  
10 429 flows in the scour hole on the right bank (as illustrated by the vector field and the increase in the  
11 430 magnitude of the reference vector) is caused by the large magnitude of flow within the scour hole  
12 431 in transect 7 with significant secondary flows of up to  $0.7 \text{ ms}^{-1}$ . In general, stronger secondary  
13 432 flows were observed in the scour hole along the right bank in transects 4-8 compared to the first  
14 433 three transects. The apparent impingement of these secondary flow vectors upon the bed is due,  
15 434 in part, to the streamwise variation in depth combined with the topographic steering of flow into the  
16 435 scour hole oriented at 15 degrees to the cross-section (see Fig. 5 inset). The orientation of the  
17 436 scour hole is such that flows within this feature are steered at about 172 degrees (and down-slope  
18 437 into the hole), while the primary flow direction for the entire section is 197.3 degrees (using the  
19 438 zero net secondary discharge definition). For a primary flow velocity of  $1 \text{ ms}^{-1}$ , this 25.3 degree  
20 439 difference in flow direction is capable of producing secondary flows on the order of  $0.47 \text{ ms}^{-1}$   
21 440 oriented toward the left bank (toward the inside of the bend). Therefore, topographic steering  
22 441 within the right bank scour hole can account for the  $0.4 \text{ ms}^{-1}$  observed secondary flows near the  
23 442 bed at 290 m across the section in Figure 5e. This example illustrates that users must exercise  
24 443 care when interpreting the results from VMT. Users must consider not only the three-dimensional  
25 444 nature of the flow when analyzing two-dimensional plots, but also consider the method used to  
26 445 compute secondary flows and the morphology and geometry of the channel. While a detailed  
27 446 investigation of the number of transects required to capture the time-averaged secondary  
28 447 circulation is beyond the scope of the present paper, VMT provides the capability to efficiently  
29 448 perform such an analysis.

30 449 Figure 5, produced by the VMT analysis, clearly shows the large zone of recirculating,  
31 450 separated, flow on the eastern bank (right side of the plot) and a zone of decelerating flow close to  
32 451 the right bank (left side of the plot), whereas the secondary flow vectors, highlighted in Figure 6,  
33 452 define divergent flow through the cross-section over a central bar. Depiction of such detail in the  
34 453 transect-averaged, three-dimensional, flow processes across the entire cross-section allows  
35 454 substantive conclusions to be drawn on the sediment transport processes in the upper St. Clair  
36 455 River and the linkages between the formation and migration of the mid-channel bar (Czuba et al.,  
37 456 2011). In particular, fluid motion in the scour hole on the right side of the cross-section, which  
38 457 represents the outside of a gentle bend where flow is accelerating (Fig. 5), is characterized by  
39 458 outward-directed flow near the surface and inward-directed flow near the bed – a sign of secondary  
40

1  
2 459 circulation. Complex, three-dimensional, patterns of fluid motion are also evident on the left side of  
3 460 the cross-section where a shear layer bounds the large separation zone along the eastern bank.  
4 461 Additionally, the secondary flow vectors define divergent flow through the section over a central  
5 462 bar.  
6  
7

8 463

## 9 464 *5.2 Wabash-Embarras Confluence*

10 465 The Embarras River joins the Wabash River along a gently curving section of the Wabash River,  
11 466 which forms the border between Illinois and Indiana, USA (Fig. 7a). Data were collected at this  
12 467 confluence on May 23, 2006, using an aluminum work boat with a bow-mounted 1200 kHz Rio  
13 468 Grande ADCP and Trimble Ag132 dGPS receiver. The data-collection campaign occurred as part  
14 469 of a research project examining the influence of changes in total discharge and momentum ratio of  
15 470 the two rivers on flow structure and bed morphology within large-river confluences. A total of eight  
16 471 cross-sections were surveyed though the reach, with 4 to 5 transects being measured at each  
17 472 cross-section. Bathymetric data from each of the four ADCP beams have been extracted from the  
18 473 ADCP data sets and corrected for heading, pitch and roll and georeferenced using the VMT  
19 474 bathymetry export option. These data were used to construct a bathymetric map of the confluence  
20 475 in ArcGIS, illustrating the value of VMT for rapid processing and integration of flow and morphology  
21 476 data for analysis of process-form interactions.  
22

23 477 Patterns of depth-averaged velocity through the confluence without spatial averaging (Fig.  
24 478 7a) and with spatial averaging (Fig. 7b;  $n = 1$ ) display little to no difference. The effect of spatial  
25 479 averaging in this case is small, but plan view spatial averaging can have a large effect on the  
26 480 visualization of flows in shallow, low-velocity streams or lakes where data can be noisy (e.g. see  
27 481 later Fig. 11). The effect of spatial averaging is more pronounced when applied to velocity data in  
28 482 cross-sections (Fig. 7). At cross-section 4, despite averaging of four repeat transects, the pattern of  
29 483 secondary vectors for a Rozovskii rotation without spatial averaging is highly variable (Fig. 8a).  
30 484 Applying spatial averaging with the nearest-neighbor (i.e.  $n = 1$  for horizontal and vertical  
31 485 smoothing windows) helps define the secondary flow pattern considerably (Fig. 8b). Further  
32 486 enhancement can be achieved by choosing smoothing parameters independently in the horizontal  
33 487 and vertical directions ( $n_h = 8$ ,  $n_v = 2$ , Fig. 8c). For example, by choosing  $n_h = 8$  for the horizontal  
34 488 smoothing window, a spatial average over 8 grid points on either side of a point results in a 4 m  
35 489 smoothing window because the horizontal grid node spacing was 0.25 m (the vertical window size  
36 490 is defined by the bin size for the ADCP data and the vertical smoothing window parameter). In all  
37 491 cases, the spatial averaging is applied on the gridded data set prior to data reduction for plotting.  
38

39 492 The use of different rotations of the velocity data can facilitate analysis of the three-  
40 493 dimensional fluid motion, especially at river confluences, where flow fields are complex (Fig. 9). At  
41 494 the Embarras River-Wabash River confluence, the pattern of secondary flow vectors with no data  
42 495 rotation (Fig. 9a) reveals the entry of relatively slow-moving flow on the right from the Embarras  
43 496 River into the Wabash River, which is deflected toward the left. Because of this flow deflection, the  
44  
45  
46

59  
60

1  
2 497 cross-section is skewed in relation to the mean flow direction over much of the Wabash River,  
3 498 producing vectors oriented consistently toward the left bank. As VMT allows the user to quickly  
4 499 switch between displays of different types of secondary flow vectors by simply changing the plot  
5 500 variables, both the zero net discharge (Fig. 9b) and Rozovskii (Fig. 9c) methods can be easily  
6 501 applied, which define different patterns of secondary flow. In particular, the Rozovskii method is  
7 502 effective at revealing the development of large-scale secondary circulation at the confluence,  
8 503 characterized by opposing patterns of near-surface and near-bed fluid motion where the two flows  
9 504 meet on the right side of the cross-section (Fig. 9c). The VMT-derived results thus reveal the  
10 505 detailed three-dimensional flow patterns through the confluence and allow analysis of the  
11 506 interactions of the confluent flows, including the formation of helical motion and downwelling of fluid  
12 507 over the confluence scour (Fig. 9c).

13 508 VMT allows all velocity components to be plotted individually for analysis; moreover,  
14 509 scalars such as acoustic backscatter intensity can be plotted and overlaid by secondary flow  
15 510 vectors to examine possible relations between sediment concentration, related to backscatter  
16 511 intensity, and flow patterns (Fig. 10). The zone of strong downwelling on the right side of cross-  
17 512 section 4, illustrated by the pattern of secondary velocity vectors, corresponds well with the zone of  
18 513 negative vertical velocities as depicted by the colour scheme associated with contouring (Fig. 10a).  
19 514 A zone of high backscatter intensity, which may be indicative of high levels of suspended sediment  
20 515 transport (Dinehart and Burau 2005a,b), is associated with strong near-bed flow to the left within  
21 516 the Wabash River (Fig. 10b). On the right, the incoming flow from the Embarras River, which  
22 517 contains little suspended sediment and therefore has low values of backscatter intensity, can be  
23 518 seen mixing with the sediment-laden Wabash River.

24 519

### 25 520 *5.3 Clinton Lake*

26 521 Clinton Lake in central Illinois (USA) is a reservoir with a surface area of approximately 20.2 km<sup>2</sup>  
27 522 and serves as a cooling pond for Clinton Nuclear Power Station. Cooling water is withdrawn from  
28 523 the west arm of the lake at a rate of approximately 42.5 m<sup>3</sup>s<sup>-1</sup> and discharged into the east arm of  
29 524 the lake at a temperature approximately 20 degrees Celsius warmer than the intake temperature  
30 525 (Figure 11a). The cycling of water through the plant creates a continuous circulation in the lake  
31 526 from the discharge outfall back to the intakes. Waste heat is dissipated to the atmosphere and  
32 527 dispersed in the lake as the thermal plume spreads through the surface water. The circulation  
33 528 induced by the plant was measured in 2008 using a 1200 kHz Rio Grande ADCP and visualized  
34 529 using VMT to better understand the lake dynamics and thermal conditions in late summer under  
35 530 normal power-station operating conditions.

36 531 VMT was used to average repeat transects collected along cross-sections spaced  
37 532 approximately 600 m apart throughout the lake (Fig. 11). In addition, a stand-alone utility in the  
38 533 VMT toolbox (ASCII2GIS) was used to extract the georeferenced water temperature data from the  
39 534 ADCP (used by the ADCP for calculation of sound velocity). The temperature data were imported

1  
2 535 into ArcGIS and gridded over the study domain using ordinary kriging. In order to capture the  
3 536 circulation patterns in the thermal plume, the upper 2.5 m of the water column was layer-averaged  
4  
5 537 in VMT and treated separately from the remainder of the water column. Plan-view plots showing  
6  
7 538 layer-averaged velocity vectors (with a vector spacing of 7.5 m) overlaid on the surface water  
8  
9 539 temperature distribution are shown for a portion of Clinton Lake downstream of the thermal effluent  
10  
11 540 outfall (Fig. 11a). The results reveal how an embankment traversing the lake constricts the  
12  
13 541 circulation of the thermal plume through two relatively small openings that generate relatively high  
14  
15 542 velocities ( $0.30 \text{ ms}^{-1}$  surface velocity and  $0.06 \text{ ms}^{-1}$  depth-averaged velocity). Immediately  
16  
17 543 downstream of the bridge openings, the plume hugs the north bank of the lake – a pattern that may  
18  
19 544 be linked to above-average bank retreat observed along this shoreline (W. Hafiz, Exelon  
20  
21 545 Corporation, personal communication). The plume then detaches from the north bank and  
22  
23 546 meanders across the lake to the outside of the bend, following a similar path to the creek that once  
24  
25 547 flowed through this river valley.

26  
27 548 The power of layer-averaging in VMT is apparent when the pattern of flow in Clinton Lake  
28  
29 549 below a depth of 2.5 m is examined (Figure 11b). As the thermal plume spreads through the lake, it  
30  
31 550 grows in size by entraining ambient water. This entrainment is greatest where high velocities and  
32  
33 551 turbulence help drive mixing, such as near the outfall and the bridge constrictions. In order to  
34  
35 552 satisfy continuity, water entrained into the thermal plume is replaced by water from elsewhere in  
36  
37 553 the lake, thus driving a deep circulation at the lake bottom. Cool, deep water is driven along the  
38  
39 554 lake bed in a direction opposite to that of the plume-induced surface current, until it reaches the  
40  
41 555 mixing zone at the bridge constriction where it is arrested and entrained into the surface current  
42  
43 556 (Fig. 11b). Computing a depth-averaged velocity at Clinton Lake using ADCP data for the entire  
44  
45 557 water column would not capture this deep circulation and would significantly reduce the magnitude  
46  
47 558 of the true thermal plume velocities. VMT thus easily gives the user complete freedom to depth- or  
48  
49 559 layer- average the data over either the full depth of the measured flow or any portion of the  
50  
51 560 measured water column.

## 562 **6.0 Summary and future developments**

563 This paper details the Velocity Mapping Toolbox (VMT), a new freely-available (open-source)  
564 toolbox for the post-processing and visualization of ADCP data collected along single or multiple  
565 transects, and illustrates its capabilities using data for three case studies. The toolbox is available  
566 to download from the USGS Hydroacoustics Web pages  
567 (<http://hydroacoustics.usgs.gov/movingboat/VMT/VMT.shtml>). The basic processing steps in VMT  
568 include defining an average cross-section orientation, defining an interpolation grid, projecting  
569 ADCP data for individual transects onto the plane of the cross-section, interpolating data for  
570 individual transects onto the grid nodes, averaging data for multiple transects at the grid nodes,  
571 calculating secondary flow vectors and depth-averaged velocities, and data smoothing through  
572 spatial-averaging. Once processing is complete, a wide range of display options are available for

1 573 exploring in detail the three-dimensional patterns of fluid motion in complex natural environments.  
2  
3 574 The toolbox should be useful for a wide range of applications where flow measurements are  
4  
5 575 conducted along transects using ADCPs. Improvements and advanced processing extensions for  
6  
7 576 VMT are currently (2012) under development that will improve data filtering, allow users to import  
8  
9 577 data from a wide range of ADCPs, use the standard output from VMT to compute estimates of  
10  
11 578 vorticity, shear velocity, bed shear stress, the longitudinal dispersion coefficient, and suspended  
12  
13 579 sediment concentrations (with a sediment calibration option for acoustic backscatter). In addition,  
14  
15 580 scripts that will allow spatial positioning of ADCP data collected without GPS and automated  
16  
17 581 routines to interpolate missing data in ADCP files are also currently under evaluation. Future  
18  
19 582 versions of VMT will incorporate some or all of these advanced capabilities and we anticipate that  
20  
21 583 the user community, with access to the open source code, will contribute to the evolution of VMT  
22  
23 584 over time.

24 585

25 586

### 26 587 **Acknowledgements**

27 588 DP and JB would like to thank the UK Natural Environment Research Council (NERC) for award of  
28 589 grants NER/A/S/2001/00445 and NER/B/S/2003/00243 that enabled the initial development of this  
29 590 code, and the World Universities Network for funding a research visit for DP to Illinois where the  
30 591 majority of the analysis was performed. DP also thanks NERC for his Fellowship funding  
31 592 (NE/C002636) that enabled further development of this research. The authors kindly acknowledge  
32 593 support of the USGS Office of Surface Water for funding the primary development of VMT and the  
33 594 many contributors to code who helped expand and improve the capabilities of this toolbox including  
34 595 those that shared their work via the Matlab Central File Exchange. Work on VMT by Bruce Rhoads,  
35 596 Frank Engel and Jim Riley was supported by National Science Foundation (NSF) grants BCS  
36 597 04533 6, BCS 06229 6, and BCS 003622.

2 792 **Figure Captions**

3 793 Figure 1: The VMT GUI interface with five sections including: i) data import; ii) graphics export, iii)  
4 794 processing options; iv) bathymetry export; and v) plotting options for both planform and cross-  
5 795 section views.  
6 796

7 797  
8 798 Figure 2: ADCP ensembles from section 2 of the Wabash-Embarras confluence (see Fig. 5)  
9 799 mapped to an average cross-section line in the VMT averaging procedure. Cross-section line  
10 800 (green line); ship tracks (blue lines); ensembles (blue circles); uniform mean cross-section grid  
11 801 nodes (black "+").  
12 802

13 803  
14 804 Figure 3: Schematic representation of the transect-averaging procedure employed by VMT during  
15 805 data processing.  
16 806

17 807  
18 808 Figure 4: Schematic diagram of the spatial-averaging procedures employed by VMT during data  
19 809 visualization with parameter settings available: horizontal smoothing window size,  $n_h$ , and a vertical  
20 810 smoothing window size  $n_v$ .  
21 811

22 812  
23 813 Figure 5: The planform distribution of depth-averaged flow velocity (in  $\text{ms}^{-1}$ ) in the upper St. Clair  
24 814 River (MI, USA). Vector length and colour correspond to flow velocity. Vectors were obtained from  
25 815 the processing and averaging procedure in VMT. Inset figure shows multibeam bathymetry in the  
26 816 vicinity of cross-section 9 from Czuba et al. (2011).  
27 817

28 818  
29 819 Figure 6: Distribution of primary and secondary velocities (in  $\text{ms}^{-1}$ ) for cross-section 9 of the upper  
30 820 St. Clair River (MI, USA). Secondary flows were computed using the zero net cross stream  
31 821 discharge definition. Panels show average flow fields for (a) one; (b) two; (c) four; (d) six and (e)  
32 822 eight ADCP transects. Interpolation and spatial averaging was held constant between panels.  
33 823

34 824  
35 825 Figure 7: The planform distribution of depth-averaged flow velocity (in  $\text{ms}^{-1}$ ) at the confluence of  
36 826 the Wabash and Embarras Rivers (IL, USA) on May 23, 2006. Velocity vectors have been overlain  
37 827 on bathymetry data extracted from the ADCP data using VMT. Panels show the depth-averaged  
38 828 velocity with (a) no spatial averaging and (b) with data averaged with its nearest neighbour  
39 829 (horizontal smoothing window of 1).  
40 830

41 831  
42 832 Figure 8: The distribution of primary velocity (denoted by colour shading, in  $\text{ms}^{-1}$ ) at cross-section 4  
43 833 (see Figure 7), with secondary (applying a Rozovskii secondary circulation rotation) and vertical  
44 834 velocities superimposed as vectors illustrating the cross-stream velocity field, at the Wabash-  
45 835 Embarras confluence (IL, USA). The mapped velocities are from 4 individual transects and plotted

1  
2 829 with (a) no smoothing; (b) light smoothing (horizontal smoothing window of 1 and a vertical  
3 830 smoothing window of 1); and (c) enhanced smoothing (horizontal smoothing window of 8 and a  
4 831 vertical smoothing window of 2). The view is looking downstream with inflow from the Embarras  
5 832 River on the right of the cross-section. The secondary and vertical velocities are scaled with no  
6 833 vertical exaggeration.

7  
8  
9 834

10  
11 835 Figure 9: The distributions of streamwise and primary velocity (denoted by colour shading, in  $\text{ms}^{-1}$ )  
12 836 at cross-section 4 of the Wabash-Embarras confluence (IL, USA; see Figure 7), with superimposed  
13 837 vectors illustrating the vertical velocity and (a) the cross-stream velocity field; (b) the transverse  
14 838 velocity field computed using the zero net secondary discharge method; and (c) the transverse  
15 839 velocity field computed using the Rozovskii method. Mapped velocities are from 4 individual  
16 840 transects and are plotted with enhanced smoothing (horizontal smoothing window of 8 and a  
17 841 vertical smoothing window of 2). The view is looking downstream with inflow from the Embarras  
18 842 River on the right of the cross-section. The secondary and vertical velocities are scaled with no  
19 843 vertical exaggeration.

20  
21  
22  
23 844

24  
25  
26 845 Figure 10: The distribution of (a) vertical velocity (denoted by colour shading, in  $\text{ms}^{-1}$ ) and (b)  
27 846 acoustic backscatter (denoted by colour shading, in db) at cross-section 4 of the Wabash-  
28 847 Embarras river confluence (IL, USA; see Figure 7). Superimposed on each plot are vectors  
29 848 illustrating the vertical velocity and the transverse velocity field computed using the Rozovskii  
30 849 definition. Mapped velocities are from 4 individual transects and are plotted with enhanced  
31 850 smoothing (horizontal smoothing window of 8 and a vertical smoothing window of 2). The view is  
32 851 looking downstream with inflow from the Embarras River on the right of the cross-section. The  
33 852 secondary and vertical velocities are scaled with no vertical exaggeration.

34  
35  
36  
37 853

38  
39  
40 854 Figure 11: The planform distribution of layer-averaged velocity (in  $\text{ms}^{-1}$ ) for Clinton Lake in central  
41 855 Illinois (USA) for layers: (a) 0 to 2.5 m depth from the water surface and (b) below 2.5 m depth  
42 856 from the water surface. The raw ADCP data was gridded to a 0.50 m horizontal grid node spacing  
43 857 and averaged for reciprocal transects prior to visualization. Vector spacing in both figures is 7.5 m.  
44 858 Background imagery includes the distribution of surface water temperature ( $^{\circ}\text{C}$ ) as measured by  
45 859 the ADCP thermistor. Temperature data were extracted using VMT (ASCII2GIS stand-alone utility)  
46 860 and gridded using kriging in ArcGIS®.

**Step 1.** Define the average cross section orientation and grid

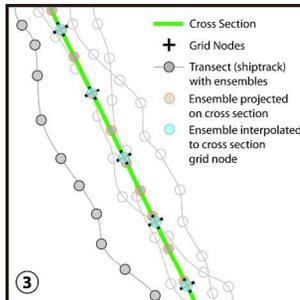

Options:

1. Least-squares fit of data cloud
2. User-defined end points

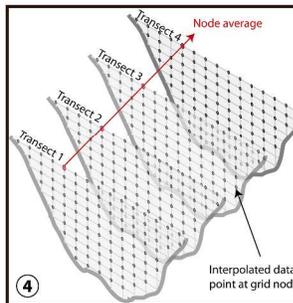

**Step 2.** Project transect data to the cross section plane using an orthogonal translation

**Step 3.** Interpolate projected data to the cross section grid for each transect (no interpolation in vertical is required when using a vertical grid defined by the bin size)

**Step 4.** Compute arithmetic average of all transects at each grid node for basic variables (e.g. velocity components)
